Learning Objectives

- To understand the 3D representation of electronic orbitals

An orbital is the quantum mechanical refinement of Bohr’s orbit. In contrast to his concept of a simple circular orbit with a fixed radius, orbitals are mathematically derived regions of space with different probabilities of containing an electron.

One way of representing electron probability distributions was illustrated previously for the 1s orbital of hydrogen. Because $\Psi^2$ gives the probability of finding an electron in a given volume of space (such as a cubic picometer), a plot of $\Psi^2$ versus distance from the nucleus ($r$) is a plot of the probability density. The 1s orbital is spherically symmetrical, so the probability of finding a 1s electron at any given point depends only on its distance from the nucleus. The probability density is greatest at $r = 0$ (at the nucleus) and decreases steadily with increasing distance. At very large values of $r$, the electron probability density is very small but not zero.

In contrast, we can calculate the radial probability (the probability of finding a 1s electron at a distance $r$ from the nucleus) by adding together the probabilities of an electron being at all points on a series of spherical shells of radius $r_1$, $r_2$, $r_3$, …, $r_x$, $r_x$. In effect, we are dividing the atom into very thin concentric shells, much like the layers of an onion (Figure \(\PageIndex{1a}\)), and calculating the probability of finding an electron on each spherical shell. Recall that the electron probability density is greatest at $r = 0$ (Figure \(\PageIndex{1b}\)), so the density of dots is greatest for the smallest spherical shells in part (a) in Figure \(\PageIndex{1}\). In contrast, the surface area of each spherical shell is equal to $4\pi r^2$, which increases very rapidly with increasing $r$ (Figure \(\PageIndex{1c}\)). Because the surface area of the spherical shells increases more rapidly with increasing $r$ than the electron probability density decreases, the plot of radial probability has a maximum at a particular distance (Figure \(\PageIndex{1d}\)). Most important, when $r$ is very small, the surface area of a spherical shell is so small that the total probability of finding the electron close to the nucleus is very low; at the nucleus, the electron probability vanishes (Figure \(\PageIndex{1d}\)).

Figure \(\PageIndex{1}\): Most Probable Radius for the Electron in the Ground State of the Hydrogen Atom. (a) Imagine dividing the atom’s total volume into very thin concentric shells as shown in the onion drawing. (b) A plot of electron probability density $\Psi^2$ versus $r$ shows that the electron probability density is greatest at $r = 0$ and falls off smoothly with increasing $r$. The density of the dots is therefore greatest in the innermost shells of the onion. (c) The surface area of each shell, given by $4\pi r^2$, increases rapidly with increasing $r$. (d) If we count the number of dots in each spherical shell, we obtain the total probability of finding the electron at a given value of $r$. Because the surface area of each shell increases more rapidly with increasing $r$ than the electron probability density decreases, a plot of electron probability versus $r$ (the radial probability) shows a peak. This peak corresponds to the most probable radius for the electron, 52.9 pm, which is exactly the radius predicted by Bohr’s model of the hydrogen atom.
For the hydrogen atom, the peak in the radial probability plot occurs at $r = 0.529$ Å (52.9 pm), which is exactly the radius calculated by Bohr for the $n = 1$ orbit. Thus the most probable radius obtained from quantum mechanics is identical to the radius calculated by classical mechanics. In Bohr’s model, however, the electron was assumed to be at this distance 100% of the time, whereas in the Schrödinger model, it is at this distance only some of the time. The difference between the two models is attributable to the wavelike behavior of the electron and the Heisenberg uncertainty principle.

Figure \(\PageIndex{2}\) compares the electron probability densities for the hydrogen 1s, 2s, and 3s orbitals. Note that all three are spherically symmetrical. For the 2s and 3s orbitals, however (and for all other s orbitals as well), the electron probability density does not fall off smoothly with increasing $r$. Instead, a series of minima and maxima are observed in the radial probability plots (Figure \(\PageIndex{2c}\)). The minima correspond to spherical nodes (regions of zero electron probability), which alternate with spherical regions of nonzero electron probability. The existence of these nodes is a consequence of changes of wave phase in the wavefunction $\Psi$.

**s Orbitals (l=0)**

Three things happen to s orbitals as $n$ increases (Figure \(\PageIndex{2}\)):

1. They become larger, extending farther from the nucleus.
2. They contain more nodes. This is similar to a standing wave that has regions of significant amplitude separated by nodes, points with zero amplitude.
3. For a given atom, the s orbitals also become higher in energy as $n$ increases because of their increased distance from the nucleus.
Orbitals are generally drawn as three-dimensional surfaces that enclose 90% of the electron density, as was shown for the hydrogen 1s, 2s, and 3s orbitals in part (b) in Figure \(\PageIndex{2}\)). Although such drawings show the relative sizes of the orbitals, they do not normally show the spherical nodes in the 2s and 3s orbitals because the spherical nodes lie inside the 90% surface. Fortunately, the positions of the spherical nodes are not important for chemical bonding.

\section*{p Orbitals (l=1)}

Only s orbitals are spherically symmetrical. As the value of \(l\) increases, the number of orbitals in a given subshell increases, and the shapes of the orbitals become more complex. Because the 2p subshell has \(l = 1\), with three values of \(m_l\) (−1, 0, and +1), there are three 2p orbitals.

The electron probability distribution for one of the hydrogen 2p orbitals is shown in Figure \(\PageIndex{3}\)). Because this orbital has two lobes of electron density arranged along the z axis, with an electron density of zero in the xy plane (i.e., the xy plane is a nodal plane), it is a \(2p_z\) orbital. As shown in Figure \(\PageIndex{4}\)), the other two 2p orbitals have identical shapes, but they lie along the x axis (\(2p_x\)) and y axis (\(2p_y\)), respectively. Note that each \(p\) orbital has just one nodal plane. In each case, the phase of the wave function for each of the 2p orbitals is positive for the lobe that points along the positive axis and negative for the lobe that points along the negative axis. It is important to emphasize that these signs correspond to the phase of the wave that describes the electron motion, not to positive or negative charges.
The hydrogen atom has two electron shells. The first shell, or K shell, is composed of the 1s subshell. The second shell, or L shell, contains the 2s and 2p subshells.

The 1s subshell consists of a single s orbital, which is spherically symmetrical and has a spherical electron probability distribution. The 2s subshell, on the other hand, has two lobes, one in the x,y plane and one in the y,z plane, with a nodal plane along the z-axis. The 2p subshell consists of three lobes, two in the x,y plane and one in the y,z plane, with nodal planes along the x and z axes.

The 2p subshell is further divided into three orbitals: 2px, 2py, and 2pz. Each of these orbitals has a maximum electron population of 2. The 2px and 2py orbitals are degenerate and have the same energy. The 2pz orbital is non-degenerate and has a slightly lower energy.

The electron probability distribution for the 2p orbitals is shown in the figure. The probability distribution is concentrated in the x,y and y,z planes for the 2px and 2py orbitals, respectively. The 2pz orbital has a higher probability density in the z direction.

The 3d subshell consists of five orbitals: 3dxy, 3dxz, 3dyz, and 3dz2. These orbitals are degenerate and have the same energy. The 3dz2 orbital is unique in that it has a nodal plane in the xy plane. The electron probability distribution for the 3d orbitals is shown in the figure.

The 4p subshell consists of four orbitals: 4px, 4py, and 4pz. These orbitals are degenerate and have the same energy. The 4pz orbital is unique in that it has a nodal plane in the z direction. The electron probability distribution for the 4p orbitals is shown in the figure.

The electron probability distribution for the 5p subshell is shown in the figure. The probability distribution is concentrated in the x,y and y,z planes for the 5px and 5py orbitals, respectively. The 5pz orbital has a higher probability density in the z direction.

The electron probability distribution for the 6p subshell is shown in the figure. The probability distribution is concentrated in the x,y and y,z planes for the 6px and 6py orbitals, respectively. The 6pz orbital has a higher probability density in the z direction.

The electron probability distribution for the 7p subshell is shown in the figure. The probability distribution is concentrated in the x,y and y,z planes for the 7px and 7py orbitals, respectively. The 7pz orbital has a higher probability density in the z direction.

The electron probability distribution for the 8p subshell is shown in the figure. The probability distribution is concentrated in the x,y and y,z planes for the 8px and 8py orbitals, respectively. The 8pz orbital has a higher probability density in the z direction.

The electron probability distribution for the 9p subshell is shown in the figure. The probability distribution is concentrated in the x,y and y,z planes for the 9px and 9py orbitals, respectively. The 9pz orbital has a higher probability density in the z direction.
contrast to p orbitals, the phase of the wave function for d orbitals is the same for opposite pairs of lobes. As shown in Figure \(\PageIndex{5}\), the phase of the wave function is positive for the two lobes of the \(dz^2\) orbital that lie along the z axis, whereas the phase of the wave function is negative for the doughnut of electron density in the xy plane. Like the s and p orbitals, as n increases, the size of the d orbitals increases, but the overall shapes remain similar to those depicted in Figure \(\PageIndex{5}\).

**f Orbitals (l=3)**

Principal shells with \(n = 4\) can have subshells with \(l = 3\) and \(m_l\) values of \(-3, -2, -1, 0, +1, +2,\) and \(+3\). These subshells consist of seven f orbitals. Each f orbital has three nodal surfaces, so their shapes are complex. Because f orbitals are not particularly important for our purposes, we do not discuss them further, and orbitals with higher values of \(l\) are not discussed at all.

**Orbital Energies**

Although we have discussed the shapes of orbitals, we have said little about their comparative energies. We begin our discussion of orbital energies by considering atoms or ions with only a single electron (such as H or He\(^+\)).

The relative energies of the atomic orbitals with \(n \leq 4\) for a hydrogen atom are plotted in Figure \(\PageIndex{6}\); note that the orbital energies depend on *only* the principal quantum number \(n\). Consequently, the energies of the 2s and 2p orbitals of hydrogen are the same; the energies of the 3s, 3p, and 3d orbitals are the same; and so forth. Quantum mechanics predicts that in the hydrogen atom, all orbitals with the same value of \(n\) (e.g., the three 2p orbitals) are degenerate, meaning that they have the same energy. The orbital energies obtained for hydrogen using quantum mechanics are exactly the same as the allowed energies calculated by Bohr. In contrast to Bohr's model, however, which allowed only one orbit for each energy level, quantum mechanics predicts that there are 4 orbitals with different electron density distributions in the \(n = 2\) principal shell (one 2s and three 2p orbitals), 9 in the \(n = 3\) principal shell, and 16 in the \(n = 4\) principal shell. The different values of \(l\) and \(m_l\) for the individual orbitals within a given principal shell are not important for understanding the emission or absorption spectra of the hydrogen atom under most conditions, but they do explain the splittings of the main lines that are observed when hydrogen atoms are placed in a magnetic field. Figure \(\PageIndex{6}\) shows that the energy levels become closer and closer together as the value of \(n\) increases, as expected because of the \(1/n^2\) dependence of orbital energies.
Figure \(\PageIndex{6}\): Orbital Energy Level Diagram for the Hydrogen Atom with a single electron. Each box corresponds to one orbital. Note that the difference in energy between orbitals decreases rapidly with increasing values of \(n\).

The energies of the orbitals in any species with only one electron can be calculated by a minor variation of Bohr’s equation, which can be extended to other single-electron species by incorporating the nuclear charge \(Z\) (the number of protons in the nucleus):

\[
E = -\frac{Z^2}{n^2} R \hbar c \quad \text{(6.6.1)}
\]

In general, both energy and radius decrease as the nuclear charge increases. Thus the most stable orbitals (those with the lowest energy) are those closest to the nucleus. For example, in the ground state of the hydrogen atom, the single electron is in the 1s orbital, whereas in the first excited state, the atom has absorbed energy and the electron has been promoted to one of the \(n = 2\) orbitals. In ions with only a single electron, the energy of a given orbital depends on only \(n\), and all subshells within a principal shell, such as the \((p_x, p_y, p_z)\) orbitals, are degenerate.

### Summary

The four chemically important types of atomic orbital correspond to values of \(\ell = 0\), \(1\), \(2\), and \(3\). Orbitals with \(\ell = 0\) are s orbitals and are spherically symmetrical, with the greatest probability of finding the electron occurring at the nucleus. All orbitals with values of \(n > 1\) and \(\ell = 0\) contain one or more nodes. Orbitals with \(\ell = 1\) are p orbitals and contain a nodal plane that includes the nucleus, giving rise to a dumbbell shape. Orbitals with \(\ell = 2\) are d orbitals and have more complex shapes with at least two nodal surfaces. Orbitals with \(\ell = 3\) are f orbitals, which are still more complex.

Because its average distance from the nucleus determines the energy of an electron, each atomic orbital with a given
set of quantum numbers has a particular energy associated with it, the orbital energy.

\[ E = -\frac{Z^2}{n^2}Rhc \nonumber \]

In atoms or ions with only a single electron, all orbitals with the same value of \( n \) have the same energy (they are degenerate), and the energies of the principal shells increase smoothly as \( n \) increases. An atom or ion with the electron(s) in the lowest-energy orbital(s) is said to be in its ground state, whereas an atom or ion in which one or more electrons occupy higher-energy orbitals is said to be in an excited state.
