In addition to precipitation and acid-base reactions, a third important class called oxidation-reduction reactions is often encountered in aqueous solutions. The terms reduction and oxidation are usually abbreviated to redox. Such a reaction corresponds to the transfer of electrons from one species to another.

A simple redox reaction occurs when copper metal is immersed in a solution of silver nitrate. The solution gradually acquires the blue color characteristic of the hydrated Cu$^{2+}$ ion, while the copper becomes coated with glittering silver crystals. The reaction may be described by the net ionic Equation

\[\text{Cu(s)} + 2\text{Ag}^{+}(\text{aq}) \rightarrow \text{Cu}^{2+}(\text{aq}) + \text{Ag(s)}\]

We can regard this Equation as being made up from two hypothetical half-equations. In one, each copper atom loses 2 electrons:

\[\text{Cu} \rightarrow \text{Cu}^{2+} + 2e^{-}\]

while in the other, 2 electrons are acquired by 2 silver ions:

\[2e^{-} + 2\text{Ag}^{+} \rightarrow 2\text{Ag}\]

If these two half-equations are added, the net result is Equation $\eqref{1}$. In other words, the reaction of copper with silver ions, described by Equation $\eqref{1}$, corresponds to the loss of electrons by the copper metal, as described by half-equation $\eqref{2}$, and the gain of electrons by silver ions, as described by Equation $\eqref{3}$.

A species like copper which donates electrons in a redox reaction is called a reducing agent, or reductant. (A mnemonic for remembering this is remember, electron donor = reducing agent.) When a reducing agent donates electrons to another species, it is said to reduce the species to which the electrons are donated. In Equation $\eqref{1}$, for example, copper reduces the silver ion to silver. Consequently the half-equation

\[2\text{Ag}^{+} + 2e^{-} \rightarrow 2\text{Ag}\]

is said to describe the reduction of silver ions to silver.

Species which accept electrons in a redox reaction are called oxidizing agents, or oxidants. In Equation $\eqref{1}$ the silver ion, Ag$^{+}$, is the oxidizing agent. When an oxidizing agent accepts electrons from another species, it is said to oxidize that species, and the process of electron removal is called oxidation. The half-equation
\[\text{Cu} \rightarrow \text{Cu}^{2+} + 2e^-\] thus describes the oxidation of copper to Cu\(^{2+}\) ion.

In summary, then, when a redox reaction occurs and electrons are transferred, there is always a reducing agent donating electrons and an oxidizing agent to receive them. The reducing agent, because it loses electrons, is said to be oxidized. The oxidizing agent, because it gains electrons, is said to be reduced.

Copper is also oxidized by the oxygen present in air. The following video shows an example of this oxidation occurring.

Example \(\PageIndex{1}\) : half-equations

Write the following reaction in the form of half-equations. Identify each half-equation as an oxidation or a reduction. Also identify the oxidizing agent and the reducing agent in the overall reaction

\[\text{Zn} + 2\text{Fe}^{3+} \rightarrow \text{Zn}^{2+} + 2\text{Fe}^{2+}\]

**Solution**

The half-equations are

\[\text{Zn} \rightarrow \text{Zn}^{2+} + 2e^-\] oxidation—loss of electrons

\[2e^- + 2\text{Fe}^{3+} \rightarrow 2\text{Fe}^{2+}\] reduction—gain of electrons
Since zinc metal (Zn) has donated electrons, we can identify it as the reducing agent. Conversely, since iron(III) ion (Fe$^{3+}$) has accepted electrons, we identify it as the oxidizing agent. An alternative method of identification is to note that since zinc has been oxidized, the oxidizing agent must have been the other reactant, namely, iron(III). Also, since the iron(III) ion has been reduced, the zinc must be the reducing agent. Observe also that both the oxidizing and reducing agents are the reactants and therefore appear on the left-hand side of an Equation.

A more complex redox reaction occurs when copper dissolves in nitric acid. The acid attacks the metal vigorously, and large quantities of the red-brown gas, nitrogen dioxide (NO$_2$) are evolved. (NO$_2$ is poisonous, and so this reaction should be done in a hood.) The solution acquires the blue color characteristic of the hydrated Cu$^{2+}$ ion. The reaction which occurs is

\[
\text{Cu(s) + 2NO}_3^{-}(aq) + 4H^+(aq) \rightarrow \text{Cu}^{2+}(aq) + 2 \text{NO}_2(g) + 6\text{H}_2\text{O(l)}
\]

Merely by inspecting this net ionic Equation, it is difficult to see that a transfer of electrons has occurred. Clearly the copper metal has lost electrons and been oxidized to Cu$^{2+}$, but where have the donated electrons gone? The matter becomes somewhat clearer if we break up Equation \ref{7} into half-equations. One must be

\[
\text{Cu(s) -> Cu}^{2+}(aq) + 2e^{-}
\]

and the other is

\[
2e^{-} + 4\text{H}^+(aq) + 2\text{NO}_3^{-}(aq) \rightarrow 2\text{NO}_2(g) + 6\text{H}_2\text{O(l)}
\]
You can verify that these are correct by summing them to obtain Equation \ref{7}.

The second half-equation shows that each NO$_3^-$ ion has not only accepted an electron, but it has also accepted two protons. To further complicate matters, a nitrogen-oxygen bond has also been broken, producing a water molecule. With all this reshuffling of nuclei and electrons, it is difficult to say whether the two electrons donated by the copper ended up on an NO$_2$ molecule or on an H$_2$O molecule. Nevertheless, it is still meaningful to call this a redox reaction. Clearly, copper atoms have lost electrons, while a combination of hydronium ions and nitrate ions have accepted them. Accordingly, we can refer to the nitrate ion (or nitric acid, HNO$_3$) as the oxidizing agent in the overall reaction. half-equation \ref{9} is a reduction because electrons are accepted.
