Skills to Develop

- To understand the periodic trends and reactivity of the group 17 elements: the halogens.

Because the halogens are highly reactive, none is found in nature as the free element. Hydrochloric acid, which is a component of aqua regia (a mixture of HCl and HNO₃ that dissolves gold), and the mineral fluorspar (CaF₂) were well known to alchemists, who used them in their quest for gold. Despite their presence in familiar substances, none of the halogens was even recognized as an element until the 19th century.

Chlorine was the first halogen to be obtained in pure form. In 1774, Carl Wilhelm Scheele (the codiscoverer of oxygen) produced chlorine by reacting hydrochloric acid with manganese dioxide. Scheele was convinced, however, that the pale green gas he collected over water was a compound of oxygen and hydrochloric acid. In 1811, Scheele’s “compound” was identified as a new element, named from the Greek chloros, meaning “yellowish green” (the same stem as in chlorophyll, the green pigment in plants). That same year, a French industrial chemist, Bernard Courtois, accidentally added too much sulfuric acid to the residue obtained from burned seaweed. A deep purple vapor was released, which had a biting aroma similar to that of Scheele’s “compound.” The purple substance was identified as a new element, named iodine from the Greek iones, meaning “violet.” Bromine was discovered soon after by a young French chemist, Antoine Jérôme Balard, who isolated a deep red liquid with a strong chlorine-like odor from brine from the salt marshes near Montpellier in southern France. Because many of its properties were intermediate between those of chlorine and iodine, Balard initially thought he had isolated a compound of the two (perhaps ICl). He soon realized, however, that he had discovered a new element, which he named bromine from the Greek bromos, meaning “stench.” Currently, organic chlorine compounds, such as PVC (polyvinylchloride), consume about 70% of the Cl₂ produced annually; organobromine compounds are used in much smaller quantities, primarily as fire retardants.

A crystal of the mineral fluorite (CaF₂). The purple color of some fluorite crystals is due to small inclusions of highly oxidizing impurities, which generate detectable amounts of ozone when the crystals are crushed.

Because of the unique properties of its compounds, fluorine was believed to exist long before it was actually isolated. The mineral fluorspar (now called fluorite [CaF₂]) had been used since the 16th century as a “flux,” a low-melting-point
substance that could dissolve other minerals and ores. In 1670, a German glass cutter discovered that heating fluorspar with strong acid produced a solution that could etch glass. The solution was later recognized to contain the acid of a new element, which was named fluorine in 1812. Elemental fluorine proved to be very difficult to isolate, however, because both HF and F₂ are extraordinarily reactive and toxic. After being poisoned three times while trying to isolate the element, the French chemist Henri Moissan succeeded in 1886 in electrolyzing a sample of KF in anhydrous HF to produce a pale green gas (Figure \(\PageIndex{1}\)). For this achievement, among others, Moissan narrowly defeated Mendeleev for the Nobel Prize in Chemistry in 1906. Large amounts of fluorine are now consumed in the production of cryolite \(\text{Na}_3\text{AlF}_6\), a key intermediate in the production of aluminum metal. Fluorine is also found in teeth as fluoroapatite \([\text{Ca}_5(\text{PO}_4)_3\text{F}]\), which is formed by reacting hydroxyapatite \([\text{Ca}_5(\text{PO}_4)_3\text{OH}]\) in tooth enamel with fluoride ions in toothpastes, rinses, and drinking water.

The heaviest halogen is astatine \((\text{At})\), which is continuously produced by natural radioactive decay. All its isotopes are highly radioactive, and the most stable has a half-life of only about 8 h. Consequently, astatine is the least abundant naturally occurring element on Earth, with less than 30 g estimated to be present in Earth’s crust at any one time.

### Preparation and General Properties of the Group 17 Elements

All the halogens except iodine are found in nature as salts of the halide ions \((\text{X}^-)\), so the methods used for preparing \(\text{F}_2\), \(\text{Cl}_2\), and \(\text{Br}_2\) all involve oxidizing the halide. Reacting \(\text{CaF}_2\) with concentrated sulfuric acid produces gaseous hydrogen fluoride:

\[
\text{CaF}_2(s) + \text{H}_2\text{SO}_4(l) \rightarrow \text{CaSO}_4(s) + 2\text{HF}_2(g)
\]

Fluorine is produced by the electrolysis of a 1:1 mixture of HF and \(\text{K}^+\text{HF}_2^-\) at 60–300°C in an apparatus made of Monel, a highly corrosion-resistant nickel–copper alloy:

\[
\text{KHF}_2(\text{l}) \rightarrow \text{electrolysis}\rightarrow \text{F}_2(g) + \text{H}_2(g)
\]
Fluorine is one of the most powerful oxidants known, and both F\(_2\) and HF are highly corrosive. Consequently, the production, storage, shipping, and handling of these gases pose major technical challenges.

Although chlorine is significantly less abundant than fluorine, elemental chlorine is produced on an enormous scale. Fortunately, large subterranean deposits of rock salt (NaCl) are found around the world (Figure \(\PageIndex{2}\)), and seawater consists of about 2% NaCl by mass, providing an almost inexhaustible reserve. Inland salt lakes such as the Dead Sea and the Great Salt Lake are even richer sources, containing about 23% and 8% NaCl by mass, respectively. Chlorine is prepared industrially by the chloralkali process, which uses the following reaction:

\[
2\text{NaCl}_{(aq)} + 2\text{H}_2\text{O}_{(l)} \xrightarrow{\text{electrolysis}} 2\text{NaOH}_{(aq)} + \text{Cl}_{2(g)} + \text{H}_{2(g)} \]

Bromine is much less abundant than fluorine or chlorine, but it is easily recovered from seawater, which contains about 65 mg of Br\(^{-}\) per liter. Salt lakes and underground brines are even richer sources; for example, the Dead Sea contains 4 g of Br\(^{-}\) per liter. Iodine is the least abundant of the nonradioactive halogens, and it is a relatively rare element. Because of its low electronegativity, iodine tends to occur in nature in an oxidized form. Hence most commercially important deposits of iodine, such as those in the Chilean desert, are iodate salts such as Ca(IO\(_3\))\(_2\). The production of iodine from such deposits therefore requires reduction rather than oxidation. The process is typically carried out in two steps: reduction of iodate to iodide with sodium hydrogen sulfite, followed by reaction of iodide with additional iodate:

\[
2\text{IO}^\text{−}_{3(aq)} + 6\text{HSO}^\text{−}_{3(aq)} \rightarrow 2\text{I}^\text{−}_{(aq)} + 6\text{SO}^\text{2−}_{4(aq)} + 6\text{H}^\text{+}_{(aq)} \]
\[
5\text{I}^\text{−}_{(aq)} + \text{IO}^\text{−}_{3(aq)} + 6\text{H}^\text{+}_{(aq)} \rightarrow 3\text{I}_2(s) + 3\text{H}_2\text{O}_{(l)} \]

Because the halogens all have ns\(^2\)np\(^5\) electron configurations, their chemistry is dominated by a tendency to accept an additional electron to form the closed-shell ion (X\(^−\)). Only the electron affinity and the bond dissociation energy of fluorine differ significantly from the expected periodic trends shown in Table \(\PageIndex{1}\)). Electron–electron repulsion is important in fluorine because of its small atomic volume, making the electron affinity of fluorine less than that of chlorine. Similarly, repulsions between electron pairs on adjacent atoms are responsible for the unexpectedly low F–F bond dissociation energy. (As discussed earlier, this effect is also responsible for the weakness of O–O, N–N, and N–O bonds.)
Electrostatic repulsions between lone pairs of electrons on adjacent atoms cause single bonds between N, O, and F to be weaker than expected.

*The configuration shown does not include filled d and f subshells. †The values cited are for the six-coordinate anion (X\(^-\)).

Because it is the most electronegative element in the periodic table, fluorine forms compounds in only the −1 oxidation state. Notice, however, that all the halogens except astatine have electronegativities greater than 2.5, making their
chemistry exclusively that of nonmetals. The halogens all have relatively high ionization energies, but the energy required to remove electrons decreases substantially as we go down the column. Hence the heavier halogens also form compounds in positive oxidation states (+1, +3, +5, and +7), derived by the formal loss of ns and np electrons.

Because ionization energies decrease down the group, the heavier halogens form compounds in positive oxidation states (+1, +3, +5, and +7).

Reactions and Compounds of the Halogens

Fluorine is the most reactive element in the periodic table, forming compounds with every other element except helium, neon, and argon. The reactions of fluorine with most other elements range from vigorous to explosive; only O\(_2\), N\(_2\), and Kr react slowly. There are three reasons for the high reactivity of fluorine:

1. Because fluorine is so electronegative, it is able to remove or at least share the valence electrons of virtually any other element.
2. Because of its small size, fluorine tends to form very strong bonds with other elements, making its compounds thermodynamically stable.
3. The F–F bond is weak due to repulsion between lone pairs of electrons on adjacent atoms, reducing both the thermodynamic and kinetic barriers to reaction.

With highly electropositive elements, fluorine forms ionic compounds that contain the closed-shell F\(^-\) ion. In contrast, with less electropositive elements (or with metals in very high oxidation states), fluorine forms covalent compounds that contain terminal F atoms, such as SF\(_6\). Because of its high electronegativity and 2s\(^2\)2p\(^5\) valence electron configuration, fluorine normally participates in only one electron-pair bond. Only a very strong Lewis acid, such as AlF\(_3\), can share a lone pair of electrons with a fluoride ion, forming AlF\(_6\)^{3-}.

Oxidative strength decreases down group 17.

The halogens (X\(_2\)) react with metals (M) according to the general equation

\[ \text{M}_{(s,l)} + n\text{X}_{2(s,l,g)} \rightarrow \text{MX}_n(s,l) \]

For elements that exhibit multiple oxidation states fluorine tends to produce the highest possible oxidation state and iodine the lowest. For example, vanadium reacts with the halogens to give VF\(_5\), VCl\(_4\), VBr\(_4\), and VI\(_3\).

Metal halides in the +1 or +2 oxidation state, such as CaF\(_2\), are typically ionic halides, which have high melting points and are often soluble in water. As the oxidation state of the metal increases, so does the covalent character of the halide due to polarization of the M–X bond. With its high electronegativity, fluoride is the least polarizable, and iodide, with the lowest electronegativity, is the most polarizable of the halogens. Halides of small trivalent metal ions such as Al\(^{3+}\) tend to be relatively covalent. For example, AlBr\(_3\) is a volatile solid that contains bromide-bridged Al\(_2\)Br\(_6\) molecules. In contrast, the halides of larger trivalent metals, such as the lanthanides, are essentially ionic. For example, indium tribromide (InBr\(_3\))
and lanthanide tribromide (LnBr$_3$) are all high-melting-point solids that are quite soluble in water. As the oxidation state of the metal increases, the covalent character of the corresponding metal halides also increases due to polarization of the M–X bond.

All halogens react vigorously with hydrogen to give the hydrogen halides (HX). Because the H–F bond in HF is highly polarized (H$^{δ^+}$–F$^{δ−}$), liquid HF has extensive hydrogen bonds, giving it an unusually high boiling point and a high dielectric constant. As a result, liquid HF is a polar solvent that is similar in some ways to water and liquid ammonia; after a reaction, the products can be recovered simply by evaporating the HF solvent. (Hydrogen fluoride must be handled with extreme caution, however, because contact of HF with skin causes extraordinarily painful burns that are slow to heal.) Because fluoride has a high affinity for silicon, aqueous hydrofluoric acid is used to etch glass, dissolving SiO$_2$ to give solutions of the stable SiF$_6^{2−}$ ion.

Glass etched with hydrogen flouride. © Thinkstock

Except for fluorine, all the halogens react with water in a disproportionation reaction, where X is Cl, Br, or I:

\[
[X_{2(g,l,s)} + H_2O_{(l)} \rightarrow H^+_{(aq)} + X^−_{(aq)} + HOX_{(aq)} \label{7}\]

The most stable oxoacids are the perhalic acids, which contain the halogens in their highest oxidation state (+7). The acid strengths of the oxoacids of the halogens increase with increasing oxidation state, whereas their stability and acid strength decrease down the group. Thus perchloric acid (HOCIO$_3$, usually written as HClO$_4$) is a more potent acid and stronger oxidant than perbromic acid. Although all the oxoacids are strong oxidants, some, such as HClO$_4$, react rather slowly at low temperatures. Consequently, mixtures of the halogen oxoacids or oxoanions with organic compounds are potentially explosive if they are heated or even agitated mechanically to initiate the reaction. Because of the danger of explosions, oxoacids and oxoanions of the halogens should never be allowed to come into contact with organic compounds.

Both the acid strength and the oxidizing power of the halogen oxoacids decrease down the group.

The halogens react with one another to produce interhalogen compounds, such as ICl$_3$, BrF$_5$, and IF$_7$. In all cases,
the heavier halogen, which has the lower electronegativity, is the central atom. The maximum oxidation state and the number of terminal halogens increase smoothly as the ionization energy of the central halogen decreases and the electronegativity of the terminal halogen increases. Thus depending on conditions, iodine reacts with the other halogens to form IF\(_n\) (\(n = 1–7\)), ICl or ICl\(_3\), or IBr, whereas bromine reacts with fluorine to form only BrF, BrF\(_3\), and BrF\(_5\) but not BrF\(_7\). The interhalogen compounds are among the most powerful Lewis acids known, with a strong tendency to react with halide ions to give complexes with higher coordination numbers, such as the IF\(_8^-\) ion:
\[
[IF_{7(l)} + KF_{(s)} \rightarrow KIF_{8(s)}] \label{8}\]

All group 17 elements form compounds in odd oxidation states (−1, +1, +3, +5, +7). The interhalogen compounds are also potent oxidants and strong fluorinating agents; contact with organic materials or water can result in an explosion.

Example \(\PageIndex{1}\)

For each reaction, explain why the given products form.

a. ClF\(_3\)(g) + Cl\(_2\)(g) → 3ClF(g)
b. 2KI(s) + 3H\(_2\)SO\(_4\)(aq) → I\(_2\)(aq) + SO\(_2\)(g) + 2KHSO\(_4\)(aq) + 2H\(_2\)O(l)
c. Pb(s) + 2BrF\(_3\)(l) → PbF\(_4\)(s) + 2BrF(g)

**Given:** balanced chemical equations

**Asked for:** why the given products form

**Strategy:**

Classify the type of reaction. Using periodic trends in atomic properties, thermodynamics, and kinetics, explain why the observed reaction products form.

**Solution:**

a. When the reactants have the same element in two different oxidation states, we expect the product to have that element in an intermediate oxidation state. We have Cl\(^{3+}\) and Cl\(^0\) as reactants, so a possible product would have Cl in either the +1 or +2 oxidation state. From our discussion, we know that +1 is much more likely. In this case, Cl\(_2\) is behaving like a reductant rather than an oxidant.

b. At first glance, this appears to be a simple acid–base reaction, in which sulfuric acid transfers a proton to I\(^-\) to form HI. Recall, however, that I\(^-\) can be oxidized to I\(_2\). Sulfuric acid contains sulfur in its highest oxidation state (+6), so it is a good oxidant. In this case, the redox reaction predominates.

c. This is the reaction of a metallic element with a very strong oxidant. Consequently, a redox reaction will occur. The only question is whether lead will be oxidized to Pb(II) or Pb(IV). Because BrF\(_3\) is a powerful oxidant and fluorine is able to stabilize high oxidation states of other elements, it is likely that PbF\(_4\) will be the product. The two possible reduction products for BrF\(_3\) are BrF and Br\(_2\). The actual product will likely depend on the ratio of the reactants.
used. With excess BrF₃, we expect the more oxidized product (BrF). With lower ratios of oxidant to lead, we would probably obtain Br₂ as the product.

Exercise \(\PageIndex{1}\))

Predict the products of each reaction and write a balanced chemical equation for each reaction.

a. \(\text{CaCl}_2(s) + \text{H}_3\text{PO}_4(l) \rightarrow\)

b. \(\text{GeO}_2(s) + \text{HF}(aq) \rightarrow\)

c. \(\text{Fe}_2\text{O}_3(s) + \text{HCl}(g) \xrightarrow{\Delta} \)

d. \(\text{NaClO}_2(aq) + \text{Cl}_2(g) \rightarrow\)

Answer:

a. \(\text{CaCl}_2(s) + \text{H}_3\text{PO}_4(l) \rightarrow 2\text{HCl}(g) + \text{Ca(HPO}_4\text{)}(\text{soln})\)

b. \(\text{GeO}_2(s) + 6\text{HF}(aq) \rightarrow \text{GeF}_6^{2-}(aq) + 2\text{H}_2\text{O}(l) + 2\text{H}^+(aq)\)

c. \(\text{Fe}_2\text{O}_3(s) + 6\text{HCl}(g) \xrightarrow{\Delta} 2\text{FeCl}_3(s) + 3\text{H}_2\text{O}(g)\)

d. \(2\text{NaClO}_2(aq) + \text{Cl}_2(g) \rightarrow 2\text{ClO}_2(g) + 2\text{NaCl}(aq)\)

Summary

The halogens are highly reactive. All halogens have relatively high ionization energies, and the acid strength and oxidizing power of their oxoacids decreases down the group. The halogens are so reactive that none is found in nature as the free element; instead, all but iodine are found as halide salts with the \(X^-\) ion. Their chemistry is exclusively that of nonmetals. Consistent with periodic trends, ionization energies decrease down the group. Fluorine, the most reactive element in the periodic table, has a low F–F bond dissociation energy due to repulsions between lone pairs of electrons on adjacent atoms. Fluorine forms ionic compounds with electropositive elements and covalent compounds with less electropositive elements and metals in high oxidation states. All the halogens react with hydrogen to produce hydrogen halides. Except for \(F_2\), all react with water to form oxoacids, including the perhalic acids, which contain the halogens in their highest oxidation state. Halogens also form interhalogen compounds; the heavier halogen, with the lower electronegativity, is the central atom.
