Learning Objectives

- To understand how molecular structure affects the strength of an acid or base.

We have seen that the strengths of acids and bases vary over many orders of magnitude. In this section, we explore some of the structural and electronic factors that control the acidity or basicity of a molecule.

---

**Bond Strengths**

In general, the stronger the $\text{A–H}$ or $\text{B–H^+}$ bond, the less likely the bond is to break to form $H^+$ ions and thus the less acidic the substance. This effect can be illustrated using the hydrogen halides:

<table>
<thead>
<tr>
<th>Relative Acid Strength</th>
<th>HF</th>
<th>HCl</th>
<th>HBr</th>
<th>HI</th>
</tr>
</thead>
<tbody>
<tr>
<td>H–X Bond Energy (kJ/mol)</td>
<td>570</td>
<td>432</td>
<td>366</td>
<td>298</td>
</tr>
<tr>
<td>pKa</td>
<td>3.20</td>
<td>−6.1</td>
<td>−8.9</td>
<td>−9.3</td>
</tr>
</tbody>
</table>

The trend in bond energies is due to a steady decrease in overlap between the 1s orbital of hydrogen and the valence orbital of the halogen atom as the size of the halogen increases. The larger the atom to which H is bonded, the weaker the bond. Thus the bond between H and a large atom in a given family, such as I or Te, is weaker than the bond between H and a smaller atom in the same family, such as F or O. As a result, acid strengths of binary hydrides increase as we go down a column of the periodic table. For example, the order of acidity for the binary hydrides of **Group 16** elements is as follows, with $(pK_a)$ values in parentheses:

$$\text{H}_2\text{O} \ (14.00 = pK_w) < \text{H}_2\text{S} \ (7.05) < \text{H}_2\text{Se} \ (3.89) < \text{H}_2\text{Te} \ (2.6)$$

**Stability of the Conjugate Base**

Whether we write an acid–base reaction as $\text{AH} \rightleftharpoons \text{A}^- + \text{H}^+$ or as $\text{BH}^+ \rightleftharpoons \text{B} + \text{H}^+$, the conjugate base ($\text{A}^-$ or $\text{B}$) contains one more lone pair of electrons than the parent acid ($\text{AH}$ or $\text{BH}^+$). Any factor that stabilizes the lone pair on the conjugate base favors dissociation of $H^+$ and makes the parent acid a stronger acid. Let’s see how this explains the relative acidity of the binary hydrides of the elements in the second row of the periodic table. The observed order of increasing acidity is the following, with pKa values in parentheses:

$$\text{CH}_4 \ (50) \ll \text{NH}_3 \ (36) < \text{H}_2\text{O} \ (14.00) < \text{HF} \ (3.20)$$

Consider, for example, the compounds at both ends of this series: methane and hydrogen fluoride. The conjugate base of $\text{CH}_4$ is $\text{CH}_3^-$, and the conjugate base of $\text{HF}$ is $\text{F}^-$. Because fluorine is much more electronegative than carbon, fluorine can better stabilize the negative charge in the $\text{F}^-$ ion than carbon can stabilize the negative charge in the $\text{CH}_3^-$ ion. Consequently, $\text{HF}$ has a greater tendency to dissociate to form $\text{H}^+$ and $\text{F}^-$ than does...
methane to form \( \text{H}^+\) and \( \text{CH}_3^-\), making HF a much stronger acid than \( \text{CH}_4\).

The same trend is predicted by analyzing the properties of the conjugate acids. For a series of compounds of the general formula \( \text{HE}\), as the electronegativity of E increases, the E–H bond becomes more polar, favoring dissociation to form \( \text{E}^-\) and \( \text{H}^+\). Due to both the increasing stability of the conjugate base and the increasing polarization of the E–H bond in the conjugate acid, acid strengths of binary hydrides increase as we go from left to right across a row of the periodic table.

Acid strengths of binary hydrides increase as we go down a column or from left to right across a row of the periodic table.

The strongest acid Known: The hydrohelium Cation

The stronger acid, the weaker the covalent bond to a hydrogen atom. So the strongest acid possible is the molecule with the weakest bond. That is the hydrohelium \((1+)\) cation, \(\text{HeH}^+\), which is a positively charged ion formed by the reaction of a proton with a helium atom in the gas phase. It was first produced in the laboratory in 1925 and is isoelectronic with molecular hydrogen \(\text{H}_2\). It is the strongest known acid, with a proton affinity of 177.8 kJ/mol.

\(\text{HeH}^+\) cannot be prepared in a condensed phase, as it would protonate any anion, molecule or atom with which it were associated. However it is possible to estimate a hypothetical aqueous acidity using Hess's law:

\[
\begin{align*}
\text{HHe}^+(g) & \rightarrow \text{H}^+(g) + \text{He}(g) & +178 \text{ kJ/mol} \\
\text{HHe}^+(aq) & \rightarrow \text{HHe}^+(g) & +973 \text{ kJ/mol} \\
\text{H}^+(g) & \rightarrow \text{H}^+(aq) & -1530 \text{ kJ/mol} \\
\text{He}(g) & \rightarrow \text{He}(aq) & +19 \text{ kJ/mol} \\
\text{HHe}^+(aq) & \rightarrow \text{H}^+(aq) + \text{He}(aq) & -360 \text{ kJ/mol}
\end{align*}
\]

A free energy change of dissociation of −360 kJ/mol is equivalent to a \(pK_a\) of −63.
It has been suggested that $\text{HeH}^+$ should occur naturally in the interstellar medium, but it has not yet been detected.

**Inductive Effects**

Atoms or groups of atoms in a molecule other than those to which H is bonded can induce a change in the distribution of electrons within the molecule. This is called an inductive effect, and, much like the coordination of water to a metal ion, it can have a major effect on the acidity or basicity of the molecule. For example, the hypohalous acids (general formula $\text{HOX}$, with X representing a halogen) all have a hydrogen atom bonded to an oxygen atom. In aqueous solution, they all produce the following equilibrium:

\[
\text{HOX}^{(aq)} \rightleftharpoons \text{H}^+^{(aq)} + \text{OX}^{-{(aq)}} \label{3}
\]

The acidities of these acids vary by about three orders of magnitude, however, due to the difference in electronegativity of the halogen atoms:

<table>
<thead>
<tr>
<th>HOX</th>
<th>Electronegativity of X</th>
<th>pKa</th>
</tr>
</thead>
<tbody>
<tr>
<td>HOCl</td>
<td>3.0</td>
<td>7.40</td>
</tr>
<tr>
<td>HOBr</td>
<td>2.8</td>
<td>8.55</td>
</tr>
<tr>
<td>HOI</td>
<td>2.5</td>
<td>10.5</td>
</tr>
</tbody>
</table>

As the electronegativity of $\langle X \rangle$ increases, the distribution of electron density within the molecule changes: the electrons are drawn more strongly toward the halogen atom and, in turn, away from the H in the O–H bond, thus weakening the O–H bond and allowing dissociation of hydrogen as $\langle \text{H}^+ \rangle$.

The acidity of oxoacids, with the general formula $\langle \text{HOXO}_n \rangle$ (with $\langle n \rangle = 0–3$), depends strongly on the number of terminal oxygen atoms attached to the central atom $\langle X \rangle$. As shown in Figure $\langle \text{PageIndex}(1) \rangle$, the $\langle K_{al} \rangle$ values of the oxoacids of chlorine increase by a factor of about $\langle 10^4 \rangle$ to $\langle 10^6 \rangle$ with each oxygen as successive oxygen atoms are added. The increase in acid strength with increasing number of terminal oxygen atoms is due to both an inductive effect and increased stabilization of the conjugate base.

Any inductive effect that withdraws electron density from an O–H bond increases the acidity of the compound.

Because oxygen is the second most electronegative element, adding terminal oxygen atoms causes electrons to be drawn away from the O–H bond, making it weaker and thereby increasing the strength of the acid. The colors in Figure $\langle \text{PageIndex}(1) \rangle$ show how the electrostatic potential, a measure of the strength of the interaction of a point charge at any place on the surface of the molecule, changes as the number of terminal oxygen atoms increases. In Figure $\langle \text{PageIndex}(1) \rangle$ and Figure $\langle \text{PageIndex}(2) \rangle$, blue corresponds to low electron densities, while red corresponds to high electron densities. The oxygen atom in the O–H unit becomes steadily less red from $\langle \text{HClO}_4 \rangle$ to $\langle \text{HClO}_3 \rangle$ (also written as $\langle \text{HOClO}_3 \rangle$), while the H atom becomes steadily bluer, indicating that the electron density on the O–H unit decreases as the number of terminal oxygen atoms increases. The decrease in electron density in the O–H bond weakens it, making...
it easier to lose hydrogen as $H^+$ ions, thereby increasing the strength of the acid.

![Electrostatic Potential Maps](image)

**Figure \(\PageIndex{1}\):** The Relationship between the Acid Strengths of the Oxoacids of Chlorine and the Electron Density on the O–H Unit. These electrostatic potential maps show how the electron density on the O–H unit decreases as the number of terminal oxygen atoms increases. Blue corresponds to low electron densities, whereas red corresponds to high electron densities. Source: Chlorine oxoacids pKa values from J. R. Bowser, Inorganic Chemistry (Pacific Grove, CA: Brooks-Cole, 1993).

At least as important, however, is the effect of delocalization of the negative charge in the conjugate base. As shown in Figure \(\PageIndex{2}\), the number of resonance structures that can be written for the oxoanions of chlorine increases as the number of terminal oxygen atoms increases, allowing the single negative charge to be delocalized over successively more oxygen atoms.

Electron delocalization in the conjugate base increases acid strength.

The electrostatic potential plots in Figure \(\PageIndex{2}\) demonstrate that the electron density on the terminal oxygen atoms decreases steadily as their number increases. The oxygen atom in $\text{ClO}^-$ is red, indicating that it is electron rich, and the color of oxygen progressively changes to green in $\text{ClO}_4^-$, indicating that the oxygen atoms are becoming steadily less electron rich through the series. For example, in the perchlorate ion ($\text{ClO}_4^-$), the single negative charge is delocalized over all four oxygen atoms, whereas in the hypochlorite ion ($\text{OCl}^-$), the negative charge is largely localized on a single oxygen atom (Figure \(\PageIndex{2}\)). As a result, the perchlorate ion has no localized negative charge to which a proton can bind. Consequently, the perchlorate anion has a much lower affinity for a proton than does the hypochlorite ion, and perchloric acid is one of the strongest acids known.
As the number of terminal oxygen atoms increases, the number of resonance structures that can be written for the oxoanions of chlorine also increases, and the single negative charge is delocalized over more oxygen atoms. As these electrostatic potential plots demonstrate, the electron density on the terminal oxygen atoms decreases steadily as their number increases. As the electron density on the oxygen atoms decreases, so does their affinity for a proton, making the anion less basic. As a result, the parent oxoacid is more acidic.

Similar inductive effects are also responsible for the trend in the acidities of oxoacids that have the same number of oxygen atoms as we go across a row of the periodic table from left to right. For example, \(\text{H}_3\text{PO}_4\) is a weak acid, \(\text{H}_2\text{SO}_4\) is a strong acid, and \(\text{HClO}_4\) is one of the strongest acids known. The number of terminal oxygen atoms increases steadily across the row, consistent with the observed increase in acidity. In addition, the electronegativity of the central atom increases steadily from P to S to Cl, which causes electrons to be drawn from oxygen to the central atom, weakening the \(\text{O}\cdots\text{H}\) bond and increasing the strength of the oxoacid.

Careful inspection of the data in Table \(\PageIndex{1}\) shows two apparent anomalies: carbonic acid and phosphorous acid. If carbonic acid \((\text{H}_2\text{CO}_3)\) were a discrete molecule with the structure \(\text{HO}(\text{HO})_2\text{C}=\text{O}\), it would have a single terminal oxygen atom and should be comparable in acid strength to phosphoric acid \((\text{H}_3\text{PO}_4)\), for which pKa1 = 2.16. Instead, the tabulated value of \(\text{pK}_1\) for carbonic acid is 6.35, making it about 10,000 times weaker than expected. As we shall see, however, \(\text{H}_2\text{CO}_3\) is only a minor component of the aqueous solutions of \((\text{CO}_2)\) that are referred to as carbonic acid. Similarly, if phosphorous acid \((\text{H}_3\text{PO}_3)\) actually had the structure \(\text{HO}(\text{HO})_3\text{P}\), it would
have no terminal oxygen atoms attached to phosphorous. It would therefore be expected to be about as strong an acid as \(\text{HOCI}\) (pKa = 7.40). In fact, the \(pK_{a1}\) for phosphorous acid is 1.30, and the structure of phosphorous acid is \(\text{H}_2\text{P}=(\text{O})\text{H}\) with one H atom directly bonded to P and one \(\text{P}=(\text{O})\) bond. Thus the pKa1 for phosphorous acid is similar to that of other oxoacids with one terminal oxygen atom, such as \(\text{H}_3\text{PO}_4\). Fortunately, phosphorous acid is the only common oxoacid in which a hydrogen atom is bonded to the central atom rather than oxygen.

</tbody>
</table>

*\(\text{H}_2\text{CO}_3\) and \(\text{H}_2\text{SO}_3\) are at best minor components of aqueous solutions of \(\text{CO}_2\text{(g)}\) and \(\text{SO}_2\text{(g)}\), respectively, but such solutions are commonly referred to as containing carbonic acid and sulfuric acid, respectively.

Inductive effects are also observed in organic molecules that contain electronegative substituents. The magnitude of the electron-withdrawing effect depends on both the nature and the number of halogen substituents, as shown by the pKa values for several acetic acid derivatives:

\(\text{pK}_a\ \text{CH}_3\text{CO}_2\text{H} 4.76 < \text{CH}_2\text{ClCO}_2\text{H} 2.87 < \text{CHCl}_2\text{CO}_2\text{H} 1.35 < \text{CCl}_3\text{CO}_2\text{H} 0.66 < \text{CF}_3\text{CO}_2\text{H} 0.52\)

As you might expect, fluorine, which is more electronegative than chlorine, causes a larger effect than chlorine, and the effect of three halogens is greater than the effect of two or one. Notice from these data that inductive effects can be quite large. For instance, replacing the \(\text{CH}_3\) group of acetic acid by a \(\text{CF}_3\) group results in about a 10,000-fold increase in acidity!
Example \(\PageIndex{1}\))

Arrange the compounds of each series in order of increasing acid or base strength.

a. sulfuric acid \((H_2SO_4, \text{or } (HO)_2SO_2)\), fluorosulfonic acid \((FSO_3H, \text{or } (FSO_2OH))\), and sulfurous acid \((H_2SO_3, \text{or } (HO)_2SO)\)

b. ammonia \((NH_3)\), trifluoramine \((NF_3)\), and hydroxylamine \((NH_2OH)\)

The structures are shown here.

\[
\begin{align*}
\text{sulfurous acid} & \quad (H_2SO_3) \\
\text{trifluoramine} & \quad (NF_3) \\
\text{sulfuric acid} & \quad (H_2SO_4) \\
\text{hydroxylamine} & \quad (NH_2OH) \\
\text{fluorosulfonic acid} & \quad (FSO_3H) \\
\text{ammonia} & \quad (NH_3)
\end{align*}
\]

**Given:** series of compounds

**Asked for:** relative acid or base strengths

**Strategy:**

Use relative bond strengths, the stability of the conjugate base, and inductive effects to arrange the compounds in order of increasing tendency to ionize in aqueous solution.

**Solution:**

Although both sulfuric acid and sulfurous acid have two –OH groups, the sulfur atom in sulfuric acid is bonded to two terminal oxygen atoms versus one in sulfurous acid. Because oxygen is highly electronegative, sulfuric acid is the stronger acid because the negative charge on the anion is stabilized by the additional oxygen atom. In comparing sulfuric acid and fluorosulfonic acid, we note that fluorine is more electronegative than oxygen. Thus replacing an –OH by –F will remove more electron density from the central S atom, which will, in turn, remove electron density from the S–OH bond and the O–H bond. Because its O–H bond is weaker, \((FSO_3H)\) is a stronger acid than sulfuric acid. The predicted order of acid strengths given here is confirmed by the measured pKa values for these acids:

\[\text{pKa } H_2SO_3 < 1.85 < H_2SO_4 < FSO_3H < \text{FSO}_2OH<10\]

The structures of both trifluoramine and hydroxylamine are similar to that of ammonia. In trifluoramine, all of the hydrogen atoms in NH3 are replaced by fluorine atoms, whereas in hydroxylamine, one hydrogen atom is replaced by OH.
Replacing the three hydrogen atoms by fluorine will withdraw electron density from N, making the lone electron pair on N less available to bond to an \(H^+\) ion. Thus \(\text{NF}_3\) is predicted to be a much weaker base than \(\text{NH}_3\). Similarly, because oxygen is more electronegative than hydrogen, replacing one hydrogen atom in \(\text{NH}_3\) by \(\text{OH}\) will make the amine less basic. Because oxygen is less electronegative than fluorine and only one hydrogen atom is replaced, however, the effect will be smaller. The predicted order of increasing base strength shown here is confirmed by the measured \(pK_b\) values:

\[
pK_b\text{NF}_3—<<\text{NH}_2\text{OH} 8.06<\text{NH}_3 4.75\]

Trifluoramine is such a weak base that it does not react with aqueous solutions of strong acids. Hence its base ionization constant has never been measured.

Exercise \(\PageIndex{1}\)

Arrange the compounds of each series in order of

a. decreasing acid strength: \(\text{H}_3\text{PO}_4\), \(\text{CH}_3\text{PO}_3\text{H}_2\), and \(\text{HClO}_3\).

b. increasing base strength: \(\text{CH}_3\text{S}^−\), \(\text{OH}^−\), and \(\text{CF}_3\text{S}^−\).

**Answer a**

\(\text{HClO}_3 > \text{CH}_3\text{PO}_3\text{H}_2 > \text{H}_3\text{PO}_4\)

**Answer a**

\(\text{CF}_3\text{S}^− < \text{CH}_3\text{S}^− < \text{OH}^−\)

**Summary**

Inductive effects and charge delocalization significantly influence the acidity or basicity of a compound. The acid–base strength of a molecule depends strongly on its structure. The weaker the A–H or B–H+ bond, the more likely it is to dissociate to form an \(\text{H}^+\) ion. In addition, any factor that stabilizes the lone pair on the conjugate base favors the dissociation of \(\text{H}^+\), making the conjugate acid a stronger acid. Atoms or groups of atoms elsewhere in a molecule can also be important in determining acid or base strength through an inductive effect, which can weaken an \(\text{O}–\text{H}\) bond and allow hydrogen to be more easily lost as \(\text{H}^+\) ions.
